For this example we will make use of replication data from Ross (2004), taking only data from 1997, where we take as the dependent variable the level of good governance in a country and as explanatory variable the level of ethno-linguistic fractionalization (ELF).

Basic interpretation of ELF: If I take two random individuals in a country, how likely is it that they are from two different ethno-linguistic groups?

Dependent variable:

goodgovt

elf -0.047^{***}
(0.012)

Constant 13.423^{***}
(0.597)

Observations 87

R^2 0.162

Adjusted R^2 0.153

Residual Std. Error 3.247 (df = 85)

F Statistic 16.484^{***} (df = 1; 85)

Note: * $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$

Example: interpretation

Interpretation

Ordinary Least Squares

Model fit

References

$$goodgovt_i = 13.42 - 0.05elf_i + \varepsilon_i$$

Example: interpretation

$$goodgovt_i = 13.42 - 0.05elf_i + \varepsilon_i$$

Interpretation

Ordinary Least Squares

Model fit

References

- There is a negative relation between ethno-linguistic fractionalization and good governance.

Example: interpretation

$$goodgovt_i = 13.42 - 0.05elf_i + \varepsilon_i$$

Interpretation

Ordinary Least Squares

Model fit

References

- There is a negative relation between ethno-linguistic fractionalization and good governance.
- For every increase in ELF by 1, the good governance measure decreases by 0.05.

Example: interpretation

$$goodgovt_i = 13.42 - 0.05elf_i + \varepsilon_i$$

Interpretation

Ordinary Least Squares

Model fit

References

- There is a negative relation between ethno-linguistic fractionalization and good governance.
- For every increase in ELF by 1, the good governance measure decreases by 0.05.
- For a (hypothetical) country where the ELF is 50, the level of good governance would be $13.42 - 0.05 \times 50 = 11.07$.

The regression equation here is

$$y_i = b_0 + b_1x_i + \varepsilon_i,$$

whereby \mathbf{y} is the dependent variable, \mathbf{x} the independent variable, i an indicator of the case (country), b_0 and b_1 the model parameters, and ε the error term.

$$y_i = b_0 + b_1x_i + \varepsilon_i$$

Interpretation

Ordinary Least Squares

Model fit

References

The linear prediction given the parameters would be

$$\hat{y}_i = \hat{b}_0 + \hat{b}_1x_i.$$

The extend to which the real value differs from the predicted value is:

$$y_i - \hat{y}_i = y_i - \hat{b}_0 - \hat{b}_1x_i = e_i.$$

By this formulation, the **residuals** (\mathbf{e}) are the vertical distance between a point and the regression line (i.e. not the shortest distance between the point and the line).

To estimate the regression line, we need to estimate the parameters b_0 and b_1 .

Ordinary Least Squares (OLS) is the most common method to do so. With OLS, we estimate the parameters such that the **sum of squared residuals** are minimized.

(This is the same as minimizing the variance of the residuals.)

Once we have estimated a line, we might ask how well this line summarizes the relationship between those two variables.

A common measure is R^2 :

$$R^2 = 1 - \frac{\text{residual sum of squares}}{\text{total sum of squares}} = 1 - \frac{\sum_{i=1}^N (y_i - \hat{y}_i)^2}{\sum_{i=1}^N (y_i - \bar{y})^2}.$$

This can be interpreted as the proportion of the variation in \mathbf{y} explained by this model.

Note the relation with correlation coefficient Pearson's r : $r = \sqrt{R^2}$.
